Abstract

Retiming combined with combinational optimization is a powerful sequential synthesis method. However, this methodology has not found wide application because formal sequential verification is not practical and current simulation methodology requires the correspondence of latches disallowing any movement of latches. We present a practical verification technique which permits such sequential synthesis for a class of circuits. In particular, we require certain constraints to be met on the feedback paths of the latches involved in the retiming process. For a general circuit, we can satisfy these constraints by fixing the location of some latches, e.g., by making them observable. We show that equivalence checking after performing repeated retiming and synthesis on this class of circuit reduces to a combinational verification problem. We also demonstrate that our methodology covers a large class of circuits by applying it to a set of benchmarks and industrial designs.

1 Introduction

Many solutions to the sequential equivalence problem have been proposed in the literature which can be broadly divided into two categories. The solutions in the first category attempt to solve the general sequential equivalence problem [4, 5, 9, 15, 16]. However, due to the complexity of the problem, the proposed solutions are either limited to relatively small-sized circuits or to circuits which have undergone relatively fewer optimization transformations. In particular techniques proposed in [15, 4] rely on finding appropriate logic transformations to facilitate the equivalence checking.

The second approach is to trade off the optimization capability with the verification complexity. In this approach, sequential optimization is constrained in order to reduce the verification complexity. In the limit, by making all the latches observable, sequential synthesis reduces to combinational optimization leading to combinational verification problems. The solution proposed in [1] falls in this category.

We propose a methodology that reduces a sequential verification problem into an equivalent combinational verification problem for a class of circuits. This allows us to leverage powerful combinational verification techniques. Our method requires the next state function to be positive unate in the latch variable for each latch with a feedback path. If the original circuit does not meet these constraints, we make a minimum number of latches observable to satisfy the constraints. Thus, our methodology effectively offers another trade-off point between constraints-on-synthesis versus complexity-of-verification. Later we show this methodology allows self-loops on latches, pipelined circuits where the latches cannot be retimed to the periphery, latches trapped inside combinational blocks, with load-enabled latches, and latches that conditionally update their contents. It is worth noting that unlike techniques proposed in [15, 4] which performs the sequential equivalence checking by solving a series of combinational equivalence problems, our technique reduces the original sequential equivalence problem into a single combinational equivalence problem. Therefore our technique is more efficient because it solves a theoretically simpler problem. However it can verify circuits only after they have been appropriately modified as mentioned above.

Related to our technique, Bischoff *et al.* [2] verify the implementation of the bus interface unit for the Alpha 21264 microprocessor. They compare RTL with gates extracted from a custom transistor netlist. However, no formal framework for such verification is presented and no technique to handle circuits with feedback paths was given. Wherever applicable, we make relevant distinction with their work.

Our paper proceeds from definitions in Section 2 to the basic idea in Section 3. In Section 4 we discuss our technique for a circuit with no feedback latches and in Section 5 we extend it to circuits containing feedback latches. The details of the experimental setup and results are given in Sections 6 and 7, respectively. Due to space limitations, the proofs for some lemmas are not presented here. These proofs are published in a technical report.

2 Preliminaries

Here we present our circuit model and notion of equivalence.

2.1 Circuit Model

A sequential circuit is an acyclic interconnection of combinational gates connected to memory elements along with input and output ports. Various notions of sequential circuits typically differ in the definition of memory elements. Our memory elements are edge-triggered latches driven by the same clock (single phase) with load-enable signals. A sequential circuit is $C = (I, O, G, L)$, where $I, O, G,$ and L are sets of inputs, outputs, gates, and latches, respectively. Each latch $l \in L$ is a pair $l = (x, e)$, where x is the latch's output signal and e is its load-enable signal. A latch without a load-enable signal (a "regular latch" in this paper) has $e = 1$. Following [11], we define a latch class $cl = (e)$ to be all latches with the same load-enable signal e. This classification is important during retiming transformations, since latches can merge as the result of a move only if they belong to the same class.

2.2 Notion of Equivalence

We use the notion of **steady-state equivalence**. We do not assume a power-up initial state for the latches. Instead, we assume each latch powers up with value X. This does not prevent the design from having a reset state for some latches activated when the reset line is pulled or a reset sequence is applied. Since the latches power-up in the state X, the circuit outputs may not take a Boolean value for a given input sequence.

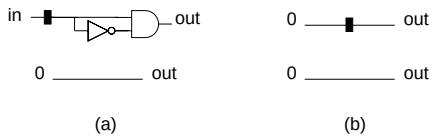

Figure 1: Example of circuits which are steady-state equivalent.

Definition 1 *For circuit C, an input sequence π is a* **steady-state input sequence** *if the exact 3-valued simulation*[1] *of C on π (the final value of all its outputs), denoted $O_C(\pi)$, results in Boolean values for all its outputs. The set of all steady-state input sequences of a circuit C is denoted as Π_C.*

Definition 2 (Steady-state equivalence) *Two circuits C_1 and C_2 are* **steady-state equivalent** *if and only if $\forall \pi, \pi \in \Pi_{C_1} \cap \Pi_{C_2} \Rightarrow O_{C_1}(\pi) = O_{C_2}(\pi)$.*

Intuitively, if an input sequence produces non-X values for the outputs of both the circuits, then the output values must match for the circuits to be steady-state equivalent. Note that this notion of equivalence is along the lines of *sufficiently old configuration* [12].

Two examples of circuits which are considered equivalent with this notion are shown in Figure 1. This notion is different from 3-valued equivalence [8] (it distinguishes both the circuit pairs in Figure 1), and exact 3-valued equivalence [14] (it distinguishes the circuits in Figure 1b).

It should be noted that the practical application of our verification technique would require that the initializability of the optimized design is verified appropriately. This would ensure that the set of steady-state input sequences is not empty leading to trivial equivalence.

In the next section we present our technique to derive a combinational representation of sequential circuits. In Section 4 we apply it to sequential circuits without feedback and add feedback in Section 5.

3 From Sequential to Combinational Representation

We reduce the problem of sequential verification to an extension of combinational verification. The goal of our technique is to obtain a canonical acyclic combinational circuit from a given sequential circuit. Towards that we use the following extensions of regular Boolean functions.

$$\begin{aligned} t &: t \in \mathbb{Z} \quad \text{Represents current time} \\ \mathbb{T} &: \{\tau \in \mathbb{Z} : \tau \leq t\} \end{aligned}$$

3.1 Clocked Boolean function

A **clocked Boolean function (CBF)** is defined for circuits containing combinational gates and regular latches. Given a circuit C, the CBF for the circuit represents the functionality of its outputs. This functionality is given in terms of input values in multiple (but finite) clock cycles.

Definition 3 *A* **clocked Boolean function** *for the output of a circuit, with n inputs and sequential depth d is a Boolean function $F : \mathbb{B}^{n*d} \mapsto \mathbb{B}$. For a signal s in the circuit, the CBF of the signal $s(t)$ at time t is defined inductively as follows:*

- *If s is the output of a gate G, the corresponding CBF is the functional composition of the CBFs of its fan-ins at the same time instant, i.e., $s(t) = f_g(y_1(t), y_2(t), \ldots, y_n(t))$, where $y_1, y_2, \ldots, y_n$ are the fan-in signals of G, and f_g represents its functionality.*
- *If s is the output of a latch, then the CBF is the value of its fan-in after one clock cycle, i.e., $s(t) = y(t \Leftrightarrow 1)$, where y is the input of the latch.*
- *If s is the primary input of the circuit, its CBF is an independent input variable $s(t)$. Note that $s(t)$ and $s(t')$ for $t \neq t'$ are different independent variables.*

[1] Similar to symbolic simulation [3] the top circuit in Figure 1a, outputs "0" in the first clock cycle.

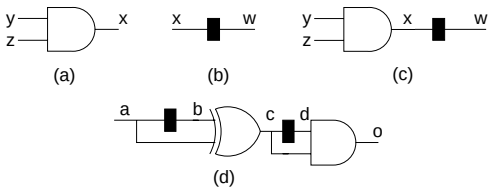

Figure 2: Some acyclic circuits.

We illustrate this concept using the following examples (Figure 2). The function f_x for the output of the AND gate is nothing but the logical AND of the functions at the input, i.e., $x(t) = y(t)z(t)$. The function for the latch is interpreted as the function of the latch input signal at the previous clock cycle, i.e., $w(t) = x(t \Leftrightarrow 1)$. If we put the latch and the AND gate together as shown in Figure 2(c), the functionality of the latch output in terms of the primary inputs is given by,

$$w(t) = x(t \Leftrightarrow 1) = y(t \Leftrightarrow 1)z(t \Leftrightarrow 1)$$

Consider the circuit given in Figure 2(d). The output function is given as:

$$\begin{aligned} o(t) &= c(t)d(t) \\ d(t) &= c(t \Leftrightarrow 1) \\ c(t) &= b(t) \oplus a(t) \\ b(t) &= a(t \Leftrightarrow 1) \\ o(t) &= (a(t \Leftrightarrow 1) \oplus a(t))(a(t \Leftrightarrow 2) \oplus a(t \Leftrightarrow 1)) \end{aligned} \quad (1)$$

Essentially, the output function depends on the value of input a in three different clock cycles. By generating three different inputs for different time instants, we can rewrite the (1) as

$$o = (a_{-1} \oplus a_0)(a_{-2} \oplus a_{-1})$$

Unlike the regular Boolean functions which give the value of a signal based on the assignment of input values for one time instant only, the CBF gives the value of a signal for input values delayed by a finite number of clock cycles. This notion is very similar to the notion of *Timed Boolean Function* given in [10] and recurrence equations in [6]. In [10], similar expressions are obtained for the signals which integrate both timing and logical functionality and generalize the conventional Boolean functions to the temporal domain. These expressions were used in timing analysis, analysis and optimization of wave-pipelined circuits, and performance validation of circuits and systems. In [6], synchronous recurrence equations were proposed for modeling and optimization of sequential circuits. However, their usage in representing and verifying the functionality of sequential circuits has not been seen before.

3.2 Event driven Boolean function

First we define some notation.

$$\begin{array}{rcll} p_i(\tau) & : & \mathbb{T} \mapsto \mathbb{B} & \text{Boolean predicates over time} \\ P & = & \{p : \mathbb{T} \mapsto \mathbb{B}\} & \text{Set of Boolean predicates} \\ \mathbb{E} & = & \bigcup_{k \geq 0} \{E : E \in P^k\} & \text{Set of events} \end{array}$$

where elements of P^k are denoted by $[p_1, p_2, \ldots, p_k]$ and an event $E \in \mathbb{E}$ is an ordered set of timed Boolean predicates.

Next we establish the time instant defined by an event. We define the function $\eta : \mathbb{E} \mapsto \mathbb{T}$ as follows:

$$\begin{array}{rcl} \eta([\,]) & = & t \quad \text{empty event denotes the current time} \\ \eta([p_1, p_2, \ldots, p_n]) & = & \begin{cases} \Leftrightarrow\infty \text{ if } A([p_1, p_2, \ldots, p_n]) = \emptyset \\ \max_\tau \{\tau \in A([p_1, p_2, \ldots, p_n])\} \\ \text{otherwise} \end{cases} \\ \text{where} & & \\ A([p_1, p_2, \ldots, p_n]) & = & \{\tau < \eta([p_2, p_3, \ldots, p_n]) : p_1(\tau)\} \end{array}$$

Intuitively, for an event $E \in \mathbb{E}$, consisting of Boolean predicates over time, $\eta(E)$ gives the most recent time instant after which all the Boolean predicates in E have been active in the order in which they are listed. If the Boolean predicates in an event cannot be active in the order they are listed, $\eta(E) = \Leftrightarrow\infty$ indicating an undefined value.

Using the η notation, we now define the next extension to a regular Boolean function.

Definition 4 *An* **event driven Boolean function (EDBF)** *is defined for circuits containing combinational gates and enabled latches. The EDBF for the output of a circuit C, with n inputs and k distinct events, is a Boolean function $f : \mathbb{B}^{n*k} \mapsto \mathbb{B}$. For a signal s in C, and an event E, the functionality of s at time $\eta(E)$ is defined inductively as follows:*

- *If s is the output of a gate G, the corresponding EDBF is the functional composition of the EDBFs of its fan-ins values associated with the same event, i.e., $s(\eta(E)) = f_g(y_1(\eta(E)), y_2(\eta(E)), \ldots, y_n(\eta(E)))$, where $y_1, y_2, \ldots, y_n$ are the fan-in signals of G and f_g represents its functionality.*
- *If s is the output of a latch with fan-in signal y and enable signal e, then it takes the most recent value of y at which e was active. This is given as $s(\eta(E)) = y(\eta([e, E]))$.*
- *If s is the primary input of the circuit, it represents an independent input variable.*

Intuitively, for a signal s and an associated event $E \in \mathbb{E}$, the EDBF $s(\eta(E))$ gives the value of s at the most recent time instant after which all the Boolean predicates in E were active in the time order consistent with the listed order.

The following examples illustrate the concept. In Figure 3(a), the value of signal y, can be represented as $x(\eta([e]))$, since the value of y is equal to the value of x at the time at which e was last active. In Figure 3(b), the functionality of signal z associated with an event E can be obtained as follows:

$$\begin{array}{rcll} z(\eta(E)) & = & y(\eta(E)) \cdot x(\eta(E)) & \\ y(\eta(E)) & = & w(\eta([e_2, E])) & \\ w(\eta([e_2, E])) & = & u(\eta([e_1, e_2, E])) & \\ x(\eta(E)) & = & v(\eta([e_3, E])) & \\ z(\eta(E)) & = & u(\eta([e_1, e_2, E])) \cdot v(\eta([e_3, E])) & (2) \end{array}$$

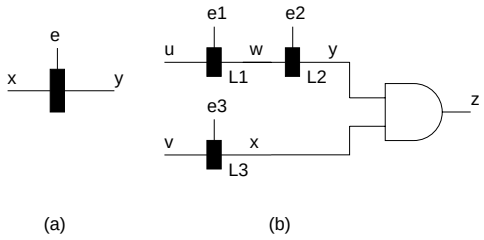

Figure 3: Combinational functionality in the presence of enabled latches: two illustrations.

Eqn. 2 indicates that the value of z is equal to the AND of the value of u which has been propagated through both latches L_1 and L_2 and of v which has been propagated through L_3.

In the next section we show how we make use of CBFs and EDBFs to obtain combinational functions for sequential circuits.

4 Sequential Circuits without Feedback

We consider sequential circuits without feedback paths (also known as "acyclic sequential circuits"). The typical circuits in this category include pipelined circuits and acyclic circuits with latches trapped within a combinational block (e.g., Figure 2d). We first explain our technique for circuits with regular latches (no load-enable signal) and then describe the case with load-enabled latches.

4.1 Circuits with Regular Latches

In this class of circuits the latches update their contents at each clock cycle. The functionality of the circuit depends on the input values possibly at multiple time instants.

We give the method to obtain the CBF for a general circuit. Given an acyclic sequential circuit C, in general, the value of a signal can be required for multiple time instants corresponding to different delays (depending on the number of latches along different paths between the signal and the primary outputs). Starting from the primary outputs, we recursively obtain the CBF for each signal as shown in Figure 4. The result of the CBF computation routine is a Boolean formula for each of the outputs in terms of the values of the inputs in multiple cycles. By treating the input values at different time instants as independent variables, we obtain a combinational function representation for the outputs of the circuit.

Figure 5 conceptually captures the functionality of the algorithm given in Figure 4.

4.1.1 Canonicity of the Formula

Theorem 4.1 (Canonicity of CBF) *Suppose C_1 and C_2 are two acyclic sequential circuits with regular latches and F_1 and F_2 their CBFs. Then $F_1 \equiv F_2 \Leftrightarrow C_1 \equiv C_2$, where equivalence between the circuits is steady-state as defined in Section 2.2, and equivalence between the CBFs is combinational.*

Proof:

$\Leftarrow$

Assume that $F_1 \not\equiv F_2$. Then there exists a CBF minterm m on the input values such that $F_1(m) \neq F_2(m)$. Since the circuit has finite depth, using this minterm m we can generate an input sequence of finite length such that when applied to the two circuits, will produce different simulation results. This implies $C_1 \not\equiv C_2$.

$\Rightarrow$

```
Compute_CBF(C){
    foreach primary output x
        Compute_CBF_Recursively (x, 0);
}
Compute_CBF_Recursively(x, d){
    if x is a primary input, return x(t − d);
    if f(x, d) is already computed, return f(x, d);
    if x is output of a latch {
        y = corresponding latch input;
        f(x, d) = Compute_CBF_Recursively(y, d + 1);
    } else{
        G_x = Gate corresponding to signal x;
        foreach fan-in y of G_x
            Compute_CBF_Recursively(y, d);
        f(x, d) = Compose the fan-in functions;
    }
    Cache the result of f(x, d);
    return f(x, d);
}
```

Figure 4: Computing the CBF for the outputs of a feedback free circuit.

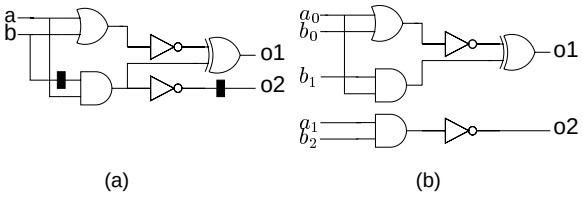

Figure 5: Generating equivalent combinational equivalence problems.

```
Compute_EDBF(C){
    foreach primary output x
        Compute_EDBF_Recursively (x, []);
}
Compute_EDBF_Recursively(x, E){
    if x is a primary input, return (x, E);
    if f(x, E) is already computed, return f(x, E);
    if x is a latch output {
        y = latch input;
        e = enable signal;
        f(x, E) = Compute_EDBF_Recursively(y, [e, E]);
    } else{
        G_x = Gate corresponding to signal x;
        foreach fan-in y of G_x
            Compute_EDBF_Recursively(y, E);
        f(x, E) = Compose the fan-in functions;
    }
    Cache the result of f(x, E);
    return F(x, E);
}
```

Figure 6: Computing EDBF for the outputs of a circuit.

Assume that $C_1 \not\equiv C_2$. Then there exists an input sequence π such that $C_1(\pi) \neq C_2(\pi)$. Since the circuits are acyclic and have finite memory, π has finite length. Using this sequence we can generate a CBF minterm such that when applied to the two formulae, will produce different results implying $F_1 \neq F_2$. Hence contradiction. ■

Note that the above result is stated for any two sequential equivalent circuits not just those obtained by retiming and combinational optimization.

4.2 Circuits with Load-enabled Latches

In the case where the latch output is controlled by an enable signal as well, the functionality is as follows: if the enable signal is high, the latch propagates the data value to the output, else the latch retains its old value. In [11], a retiming technique was proposed to handle latches with different enable signals and different clocks. In this work, we propose a verification methodology where all the latches are driven by the same clock but can have different enable signals. Extension to circuits with multiple clocks is straightforward.

We obtain a Boolean function along the lines of the previous case (regular latches). However, in this case we make use of event driven Boolean functions (EDBF) as defined in Section 3.2. By instantiating separate Boolean variables for each unique combination of primary input and event, we create a combinational representation of the circuit.

Starting from primary outputs, we recursively obtain the EDBF for each signal as shown in the Figure 6.[2]

4.2.1 Canonicity of the Formula

Theorem 4.2 (Canonicity of EDBF) *Given two acyclic sequential circuits C_1 and C_2 with load-enabled latches, such that C_2 has been obtained from C_1 by retiming and combinational synthesis transformations. Suppose F_1 and F_2 are their EDBFs, then $F_1 \equiv F_2$.*

[2]Though this algorithm was developed independently, a very similar algorithm was presented in [2]. For completeness sake, we produce it here.

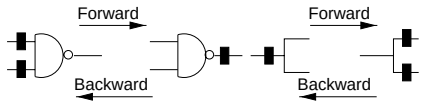

Figure 7: Primitive retiming operations. All general retiming operations can be built from a sequence of these.

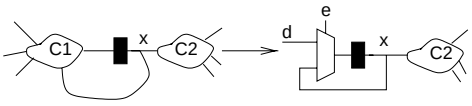

Figure 8: Modeling feedback using a latch with enable and data signals.

Proof: (sketch)
We prove this theorem by induction on the transformation steps. The combinational synthesis does not change the functionality of the circuit, trivially, EDBFs are also equivalent. For retiming steps, we show the correctness using the basic retiming moves as illustrated in Figure 7 (moving latches across NAND gates and fan-out junctions defined as primitive elements). A general retiming can be constructed as sequence of basic retiming moves. It can be easily shown that the retiming across primitive elements results in equivalent EDBFs. Since the EDBFs are obtained by recursive functional composition, two circuits that structurally differ because of a retiming move across a primitive element, will also have equivalent EDBFs. The iterative retiming moves across primitive elements also result in equivalent EDBF because of the transitivity of the EDBF equivalence. ■

Theorem 4.2 is necessary to validate the algorithm given in Figure 6 and [2]. Unlike the regular latch case, the result does not hold for any two sequentially equivalent circuits.

5 Sequential Circuits with Feedback

In these circuits there exists a feedback path for some latches. Our strategy is to model a latch with feedback in the form of a latch with feedback path with appropriate enable and data signals as shown in Figure 8. Next we derive the conditions under which this modeling is feasible.

Lemma 5.1 (Decomposition condition) *Suppose the next-state function of a latch x given as $F(x)$. Then $F(x) = e \cdot d + \bar{e}x \Leftrightarrow F_{\bar{x}} \subseteq F_x$, i.e., $F(x)$ can be decomposed in the form of Figure 8 if and only if $F(x)$ is positive unate in x. Note that e and d are independent of x.*

As a matter of fact, any d, which satisfies,

$$F_{\bar{x}} \quad \subseteq d \subseteq \quad F_x \tag{3}$$

can be used as the data signal. On the other hand, using simple Boolean algebra we can show that the value of e is unique and is given as $\bar{F}_x + F_{\bar{x}}$.

Thus for latches whose next-state function is positive unate in the latch variable, the feedback can be modeled via a multiplexer. The advantage of the model shown in Figure 8 is that a latch fed by a multiplexer can be thought of as an enabled latch as shown in the Figure 9. This gets rid of the feedback path and for our purposes the circuit becomes acyclic. Now we can apply the analysis techniques developed in Section 4.2 for acyclic circuits with enabled latches. However, we need to be aware of following issues:

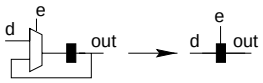

Figure 9: Modeling an enabled latch with extra logic.

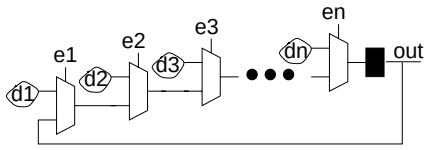

Figure 10: Conditional updating of the latch content.

1. The data-input and the enable signal both need to be independent of the latch signal, else it will create a cycle.

2. The data value d obtained from the function $F = ed + \bar{e}x$ is not unique as shown in (3) since d has e as don't care. Hence for two circuits C_1 and C_2 we can come up with different decompositions leading to false negatives. This can be handled in the following ways:

   (a) By fixing the latch modeling in the circuit, i.e., once we model the feedback path of a latch by an enabled latch, we restrict the logic optimization of the feedback logic by not using e as don't care and also, we move the latch in tandem with the logic for the enable signal. This will guarantee the event correspondence in two circuits. However, by preserving the multiplexor logic we incur some optimization penalty.

   (b) By using the lower limit of the possible data signal, i.e., $d = F_{\bar{x}}$. This guarantees the matching of the enable signals, but an optimization penalty may be incurred.

   (c) By performing a canonical decomposition of the enable and data signals. The lemma 5.2 gives a sufficient condition for such a decomposition.

Lemma 5.2 (Data-enable decomposition) *Given a function $F = Ax + B$, suppose (e, d) and $(e, \hat{d})$ are two decompositions such that e and d have disjoint Boolean supports. Then $d = \hat{d}$, i.e., there is a unique decomposition of F such that d and e have different supports (if such decomposition exists).*

The feedback modeling as derived in Figures 8 and 9 is best suited for the class of circuits where latches update their values when a set of conditions is met, else they keep their previous values. This is illustrated in Figure 10.

The latches with feedback paths, for which we cannot derive the enabled latch model, are handled in the following way. We find a minimum number of latches that need to be exposed, i.e., need to be made observable, in order to remove the feedback path for these latches. By exposing latches, we treat their outputs as primary inputs and hence the feedback paths are broken, i.e., we cut the latches from the circuit.After finding the minimal set of latches to be exposed, we impose constraints on the synthesis step such that these latches cannot be moved during retiming.

6 Experimental Setup

6.1 Circuit Modification

Given a sequential circuit C, we create a directed graph $G = (V, \vec{E})$ in the following manner. For each combinational gate, latch, primary input and primary output we create a node. An edge from node v_i to v_j is created if there is a fanout from gate/latch/primary-input i to gate/latch/primary-output j. The graph in general has cycles due to feedback paths to latches. In the current work we have not implemented the technique to identify the latches with feedback paths that satisfy the criterion mentioned in the previous section. Instead, we obtain a minimal set of latches to expose such that the circuit becomes acyclic.

6.2 Retiming

Retiming was done using *Minaret* [13]. This tool only supports the constant delay model (we could not find any efficient public domain retiming tools, that supported better delay models). Retiming was performed in two modes. First, the minimum feasible period was obtained and the area of the circuit was optimized for this period. In the second mode, the delay obtained through combinational optimization was used as the timing constraint and then constrained minimum area retiming was performed.

We could not find a retiming tool which could handle latches with enable signals as proposed in [11]. Hence, in the current work we show results on retiming of circuits with regular latches.

6.3 Combinational Optimization

We used SIS [7] to obtain a minimum delay circuit. A modified version of "script.delay" was used. The modifications were made because the original script was not able to handle large designs (or took very long to complete).

As mentioned earlier, the unit delay model was used during retiming. Hence for consistency we used the unit delay model during the synthesis steps as well. To keep the size of gates small, we created a library consisting of inverter, 2-input nand and 2-input nor gates only. Also, for reasonable optimization results we limited the number of fanouts of each gate to four. The delay models and the fanout limitation changes were achieved by appropriately modifying the library.

6.4 Generating Equivalent Combinational Equivalence Problems

In order to leverage from the existing combinational equivalence tools, we mapped the equivalence problem of CBF/EDBFs into combinational equivalence problems. This was done by creating a combinational circuit with appropriate variables which represents the CBF or EDBF as shown in Figure 5. The combinational circuit Figure 5(b) represents the CBF for the sequential circuit Figure 5(a). Essentially, if the circuit outputs depend on the value of a signal at k different time instants (for a circuit with regular latches) or with k different enable signal paths (for a circuit with enabled latches), the cone of logic for the signal is replicated k times. The size of these circuits could become large due to replications. Note, however, that this step is performed only for convenience (to treat the combinational equivalence checker as a black box). In practice, a modified combinational equivalence checker could be used which would not require generation of such circuits and hence no blow-up would occur. The combinational verification was performed by an in-house tool.

7 Experimental Results

Our experiment consisted of the following steps

1. Given the sequential circuit (A), modify it appropriately to satisfy constraints on all feedback paths to obtain a new circuit (B). This is done by creating a circuit graph and finding a minimal feedback vertex set. Due to the lack of a retiming tool which could handle load-enabled latches, we did not model any latches with feedback path as load-enabled latches (as shown in Figure 8).

2. Perform synthesis for delay optimization and min-period retiming on the modified circuit (B) to obtain a new circuit (C).

3. To illustrate the advantage of combining retiming with combinational synthesis, we also performed pure combinational optimization (using the same script) on the original circuit (A) to obtain circuit (D).

4. We also compared the savings in area by performing constrained minimum area retiming. This was done on circuit (B) with the delay value of circuit (D) to obtain a new circuit (E).

5. Combinational circuits (H and J) were created (as described in Section 6.4) from circuits (B) and (C) respectively.

6. Perform combinational verification between (H) and (J). Verifying equivalence of circuits (B) and (E) would be similar and is not done in the experiment.

The active area and delay numbers are obtained by the "map" command. The verification was performed on an UltraSparc-1 with 256MB of memory.

In Table 1, we have given results comparing the optimization potential of our strategy and also the corresponding verification times.

All the industrial circuits we investigated contained load-enabled latches. Since we did not have access to a retiming tool for circuits with load-enabled latches, we could not perform retiming on these circuits and hence could not get optimization and verification results. We performed a structural analysis of 12 industrial designs with upto 2200 latches. The percentage of latches that needed to be exposed to make the circuit acyclic ranged from 2% to 61% with an average of 36%.

7.1 Analysis

By analyzing the data given in Table 1 we make the following observations:

1. Comparing δ values in columns C and D, for most of the circuits the delay values obtained through our approach is better than that by pure combinational optimization. In some cases delay values reduce by as much as 50%. The area penalty incurred in the process is negligible.

2. Comparing area numbers in columns D and E, for the same delay, retiming allows us to reduce the area.

3. The verification times were quite reasonable. Most of the examples took less than a minute to verify. The maximum time taken is fifteen minutes. Note that, for only a few of these sequential circuits the state-space can be traversed, and for fewer yet the state-space of the product machine can be traversed. This makes the proposed technique quite attractive.

Circuit	A	C				D		E		Time

Table 1: Results on sequential optimization and verification.

A,B,C,D,E,H,J: As described in Section 7
L,%: Latches, Percentage of latches exposed in B
Area/δ: Area (normalized against D) / Delay of the circuit
H vs J: CPU time (in minutes:seconds) for combinational verification between H and J

8 Conclusions and Future Directions

We proposed a practical verification technique for circuits which have undergone retiming and combinational synthesis transformations. In particular, we show that the corresponding sequential verification can be reduced to an extension of combinational verification. The proposed technique can deal with circuits with and without feedback paths, and with regular and load-enabled latches. We impose a constraint on the feedback path (if one exists) of latches. If these constraints are not met by the original circuit, we fix the position of some of the latches to cut the feedback paths. Our strategy can be used to obtain faster circuits by allowing retiming transformations while performing fast verification, as indicated by our experimental results. Availability of a retiming tool which can move enabled latches across combinational blocks is critical for sequential optimization of industrial circuits. To make our approach exact for arbitrary sequential optimizations, we need to develop a complete technique to distinguish events and combination of events and signals.
