Abstract

In this paper, we propose a new methodology to integrate circuit transformation into routing. More specifically, this paper shows an approach for performing routing and wire reconnection simultaneously. To accomplish this, we introduce a new logic representation that implements all possible wire reconnections implicitly by enhancing global flow optimization techniques. Since our method takes into account circuit transformation during routing phase where the accurate physical information is available, we can obtain better results than the conventional routing algorithms. In addition, we can succeed in routing even if other routers like rip-up and reroute methods fail. The algorithm has been implemented and the experimental results are presented. We believe this is the first approach which combines them completely.

1. Introduction

As feature sizes decrease and chip sizes increase, the area and performance of chips become dominated by the interconnect. Since it is difficult to obtain the physical implementation until routing phase, most logic synthesis tools cannot estimate the effects of the interconnect accurately. In addition, when some nets cannot be routed properly or design doesn’t satisfy constraints in routing phase, we have to perform logic synthesis again.

Logic optimization algorithms based on rewiring techniques[1] have been developed in the last decade. The basic idea of these algorithms is to add and remove redundant wires in a circuit. Due to the incremental nature, the techniques can easily be applied to a circuit even after its placement is fixed. For performance optimization, Jiang et al. proposed a post-layout logic restructuring technique based on the rewiring technique[2]. It picks one of the rewiring , and then performs routing incrementally. In this approach, wire reconnection and routing are performed independently.

In this paper, we present an approach for performing routing and wire reconnection simultaneously. To accomplish this, we introduce a new logic representation that implements all possible wire reconnections implicitly. Since our method takes into account circuit transformation during routing phase where the accurate physical information is available, we can obtain better results than the conventional routing algorithms.

The rest of this paper is organized as follows. In the next section, we briefly review global flow optimization and exact routing methods. In Section 3, we introduce a multi-level logic representation of an implication flow graph and show how to derive all solutions from the representation. Section 4 describes our approaches to unify routing and wire reconnection. Experimental results are presented in Section 5.

2. Overview of Existing Algorithms

2.1. Global Flow Optimization

In [3], global flow optimization technique has been proposed. It gathers a circuit information using techniques of data flow analysis, and then reconnect the immediate fanouts of a node to the inputs of other nodes (so called fanout global flow optimization). Recently, Chang et al. have shown that the method cannot fully characterize a circuit and hence the optimality may be lost[4]. They have also introduced a modified technique using new graph, which is called an implication flow graph.

We briefly review the global flow optimization method using the implication flow graph. It is assumed that a circuit consists of only NOR gates. It first assigns a target node $s$ to a value 1 and then propagate it towards the primary outputs. Figure 1 illustrates the value assignments of an example circuit, where the target node is the node $s$. Next, an implication flow graph is constructed as follows.
1. Add a source node \( Src \) representing the node \( s \) and a sink node \( Snk \).

2. Add a corresponding node for a node with implication. If a node has a controlling value, the corresponding node in the implication flow graph has an IMP\_OR type with weight 1. If a node has a non-controlling value, the corresponding node has an IMP\_AND type with weight infinite.

3. Edges are added as follows. First, the IMP\_AND node is connected to all its corresponding input nodes. An IMP\_OR node is connected to all its corresponding nodes with controlling value to the node. Add the edges from all the frontier nodes to the sink node.

After building the implication flow graph, a degenerated implication flow graph is constructed by removing all but one fanin edges for each IMP\_OR node. Any cutset in the degenerated implication flow graph can form a solution for the fanout reconnection. Figure 2 shows one of the degenerated implication flow graphs derived from the circuit shown in Figure 1. Since the node 8 and 9 form a cutset of the graph, we can reconnect the immediate fanouts of the node 8 to the inputs of the node 8 and 9 in Figure 1. The resulting circuit is shown in Figure 3. Obviously, the quality of the solution heavily depends on the way how to remove fanin edges from the implication flow graph and how to obtain a cutset in the graph.

### 2.2. Exact Routing Using Symbolic Representation

In [5], Schmiedle et al. have presented an exact approach for solving channel routing problems. They have also shown a search space reduction technique[6]. They use Multi-valued Decision Diagrams (MDDs) for representation of the routing space. All possible solutions are represented in a single MDD. Figure 4 shows an example of MDD. The function \( f \) represented by this MDD satisfies \( f = 1 \) only when \((a, b, c, d) = (0, 0, 2, 1), (1, 0, 0, 2), (1, 0, 2, 0)\).

We briefly review the exact routing method. The method assumes that the grid-based model is used, i.e., the routing region are divided into rectilinear grids. In routing region, \( x \)-direction is referred to columns, \( y \)-direction to tracks and \( z \)-direction to layers. Every grid point is represented by an MDD variable \( m_{xyz} \) \( x = 1, ..., length, y = 1, ..., width, z = 1, ..., height \). Given \( N = \{N_1, ..., N_n\} \) to be routed, the set of legal values for these variables is \( \{0, ..., n\} \). \( m_{xyz} = k \) means that the routing grid at \((x, y, z)\) is occupied by net \( N_k \) and \( m_{xyz} = 0 \) means that the routing grid at \((x, y, z)\) is not occupied by any net.

For constructing the MDD representation corresponding to the set of all solutions, connectivity predicates are computed first by a fixed point iteration. A connectivity predicate \( C_{it}(p) \) indicates that \( p \) is connected with \( t \) via net \( N_i \). An iteration starts with \( C_{it}^0(t) = (t = i) \) for a terminal \( t \) and \( C_{it}^0(p) = false \) for all \( p \neq t \). In \( j \)th iteration, \( C_{ij}^j(p) \) for each grid point \( p \) is computed by the following equation

\[
C_{ij}^j(p) = C_{ij}^{j-1}(p) \lor (\bigvee_{p'}(C_{ij}^{j-1}(p') \land (m_{xyz} = i)))
\]

where \( p' \) and \( p \) are adjacent. The iteration is continued until a fixed point reaches. Then connectivity predicate \( C_{ij}(p) = C_{ij}^{\text{final}} \) is obtained. In other words, we can view this process as exploring the grid in every direction like Lee’s maze router [7] and recording all possible paths.
Figure 4. Multi-valued Decision Diagram (MDD).

An MDD \( n_i \) representing all possible paths of net \( N_i \) can be derived from the equation:

\[
n_i = \bigwedge_{j=2}^{|N_i|} C_{t_{ij}} (t_{ij})
\]

where \( t_{ij} \) is the \( j \)th terminal of net \( N_i \). Finally, the MDD representing routing solutions for all nets is obtained by combining all \( n_i \):

\[
s = \bigwedge_{N_i \in N} n_i
\]

A given routing problem is solvable if and only if \( s \neq 0 \).

3. New Logic Representation of Implication Flow Graph

In this section, we introduce a new logic representation of the implication flow graph. Since this representation contains all possible wire reconnections implicitly, we don’t have to care about how a degenerate implication flow graph is obtained. In addition, it enables us to solve a global flow optimization problem efficiently.

We can derive a logic representation from a given implication flow graph as follows.

1. Transform IMP_AND and IMP_OR nodes into AND and OR gates respectively.
2. Replace \( Snk \) node with AND gate.
3. Remove \( Src \) node and its fanout edges.
4. Create new Boolean variables which correspond to each OR gate. Each variable is inserted as the corresponding OR gate’s fanin.

Let \( t_1, \ldots, t_n \) be the new Boolean variables. Then the resulting Boolean function is represented by \( f(t_1, \ldots, t_n) \). Each input pattern which satisfies the function \( f \) corresponds to a wire reconnection. Figure 5 shows the logic representation of the implication flow graph in Figure 2. For instance, \((t_8 = 1, t_9 = 1)\) satisfies the function \( f \), then we can reconnect the immediate fanouts of the node \( s \) to the inputs of the node \( 8 \) and \( 9 \) in Figure 1.

As can easily be seen, each prime implicant of the Boolean function corresponds to a cutset of a degenerated implication flow graph. Since the function is a unate function, all prime implicants are essential and will appear in the minimized function[8]. Therefore we can use many existing two-level logic minimization algorithms in order to obtain the solutions of a global flow optimization problem. In the case of Figure 5, the function \( f \) is minimized to:

\[
f = t_1 \cdot t_2 + t_2 \cdot t_9 + t_3 \cdot t_9 + t_8 \cdot t_9
\]

and so possible rewires are \{1, 2\}, \{2, 9\}, \{3, 9\}, \{8, 9\}, i.e., the immediate fanouts of the node \( S \) in Figure 1 can be reconnected to node 1 and node 2, or node 2 and node 9, and so on.

4. Simultaneous Wire Reconnection and Routing

In this section, we present an exact approach for solving the reconnection and routing problems simultaneously. Since both problems have already been transformed into Boolean functions, unification of these two algorithms can be easily accomplished.

Our layout model is illustrated in Figure 6. There is a routing region between two parallel rows of cells with terminals at the top or bottom of the routing region. Some cells have extra terminals and the nets can be reconnected to them. It is assumed that the cells are replaced with the appropriate cells if the reconnections are performed.
At first, we create the logic representation of implication flow graph for the net $N_i$ and then obtain the Boolean formula $f(t_2, ..., t_m)$ where $t_2, ..., t_m$ are Boolean variables corresponding to the candidate terminals. To combine this Boolean formula with an exact routing, we just replace the Equation (2) with:

$$n_i = f(C_{i,t_2}, ..., C_{i,t_m})$$  \hspace{1cm} (5)

Note that we can use the multi-level logic representation of the function $f$ to calculate the Equation (5), rather than the two-level logic representation. The resulting MDD represents all possible routing solutions with consideration of wire reconnection. That is, in this framework, logical rewiring and detail routing are done simultaneously. We believe this is the first approach which combines them completely.

As shown in the original paper[5], the exact router can handle only small problems because the size of the MDDs become too large. If one’s objective is just to obtain one of the solutions, we can solve larger problems. We evaluate the Equation (3) for each connectivity predicate calculation step, and stop the calculation when any solutions are found. Using this technique, we can hope that the solutions are found before the MDDs blow up.

5. Experimental Results

The technique presented in Section 3 was implemented and we performed experiments on MCNC91 benchmark circuits. The circuits are first decomposed to only NOR gates and then the technique is applied to each wire. Each logic representation of implication flow graph is collapsed to two-level logic and minimized by ESPRESSO[8]. The number of the wire reconnections corresponds to the number of the product terms in the minimized expression. The results are shown in Table 1. The third column shows the number of the nets with one or more wire reconnections.

In column 4, the cumulated sum of the number of the wire reconnections for each net is shown. Note that the original connections are excluded from the wire reconnections. The results show that there are many wire reconnections in the circuits. For some circuits which are not shown in Table 1, such as C2670 and C3540, we couldn’t obtain the results because the resulting two-level expressions became too large. This may be avoided by using the implicit prime implicants enumeration methods like [9].

Next, the algorithm presented in Section 4 and [5] was implemented and we performed experiments on some example circuits. We consider an example circuit that consists of three nets and a routing grids with a channel that has 6 columns, 4 tracks and 2 layers as shown in Figure 7. The Boolean functions that are derived from the method described in Section 3 are as follows:

$$f_x = (b + d)eg$$  \hspace{1cm} (6)

$$f_y = cfh$$  \hspace{1cm} (7)

$$f_z = ai$$  \hspace{1cm} (8)

In Equation (6)-(8), the Boolean functions $f_x, f_y, f_z$ correspond to the terminals $x, y, z$ in Figure 7 respectively and

</table>
each Boolean variable corresponds to the terminal in Figure 7. That is, the terminal x can be connected to the terminals b, e, g or the terminals d, e, g. The terminal y must be connected to terminals c, f, h and the terminal z to the terminals a, i. We were able to find all possible solutions within 800 seconds. Figure 7 shows some of the solutions. In Figure 7 (a)(b), the terminal x is connected to the terminals b, e, g, and the terminal x is connected to the terminals d, e, g in Figure 7(c)(d).

For larger examples, the heuristic technique described in Section 4 was applied. Equation (3) in Section 2.2 are evaluated for each connectivity predicate calculation step and the calculation is stopped when any solutions are found. Table 2 shows some results for some example circuits up to 8 columns, 6 tracks, 2 layers and 3 nets. The fourth column shows the number of the evaluations of Equation (3). In column 5 and 6, memory usage and CPU time are shown respectively.

6. Conclusions and Future Work

In this paper, we first introduced a logic representation of an implication flow graph. This representation enables us to solve the global flow optimization problem efficiently. Then, we showed an exact approach for performing routing and wire reconnection simultaneously. Although the approach can handle only small portions of circuits, it allows us to explore larger solution space than the previous routing methods. In the future, we plan to integrate other routing algorithms to handle practical problems.

As mentioned earlier, the global flow optimization technique assumes that circuits consist of only NOR gates. Therefore our method cannot handle general circuits containing complex gates such as XOR, AND-OR-INVERTER, etc. An extension to general circuits is currently being investigated.
